RESEARCH MEMORANDUM

FLIGHT MEASUREMENTS OF DRAG AND BASE PRESSURE OF A

FIN-STABILIZED PARABOLIC BODY OF REVOLUTION

(NACA RM-10) AT DIFFERENT REYNOLDS NUMBERS

AND AT MACH NUMBERS FROM 0.9 TO 3.3

By H. Herbert Jackson, Charles B. Rumsey,  
and Leo T. Chauvin

SUMMARY

Free-flight tests have been made to investigate the total drag and base drag at different Reynolds numbers of full-scale and half-scale models of an NACA research model designated the RM-10. The general shape of the body was a parabola of revolution of fineness ratio 12.2 with a blunt base to provide space for the rocket jet. The models were stabilized by four  $60^\circ$  sweptback fins mounted at the base of the bodies.

The Mach number range of the tests was approximately 0.9 to 3.3. The ranges of Reynolds number, based on body length, were from  $14 \times 10^6$  to  $210 \times 10^6$  for the full-scale models and  $15 \times 10^6$  to  $110 \times 10^6$  for the half-scale models.

The results show that the total-drag coefficient for both models reached a maximum at transonic speed and gradually decreased over the entire supersonic range, while the base drags were a maximum at transonic speeds and a minimum at about Mach number 1.2 for the supersonic speed range.

It is indicated that there was at most, only small effect on the total-drag coefficient of the configuration at a given Mach number due specifically to reductions in Reynolds number of  $20 \times 10^6$  to  $120 \times 10^6$  over the Reynolds number range from  $40 \times 10^6$  to  $210 \times 10^6$ . The base-drag coefficient of the half-scale models was 25 to 50 percent lower than that of the full-scale model. The difference in base-drag coefficient would account for practically all the difference in the total-drag coefficient of the two models, indicating small effect of Reynolds number changes at a given Mach number on fore-drag coefficient over the Reynolds number range of the tests. This would be expected from the present

knowledge of skin friction in this Reynolds number range. The difference in base-drag coefficient was possibly due to either the difference in Reynolds number at a given Mach number or to differences in the internal base configuration between the full-scale and half-scale models. Part of the decrease in total-drag coefficient with increasing Mach number over the higher portion of the Mach number range was doubtless due to the reduction of skin-friction coefficient with increasing Mach number.

## INTRODUCTION

As part of an NACA program of supersonic research, the Langley Pilotless Aircraft Research Division has made a series of flight tests at its Pilotless Aircraft Research Station, Wallops Island, Va., to investigate the drag at different Reynolds numbers of a fin-stabilized parabolic-arc body of revolution designated the NACA RM-10. This investigation is part of a coordinated program including also tests of the same configuration in various wind tunnels in order to assess the effects of Reynolds number on drag characteristics. Data from the Lewis 8- by 6-foot supersonic tunnel are given in references 1 and 2. The change of Reynolds number in the present tests was obtained by using models of identical configuration but of different scale and by boosting the models to obtain various altitude-velocity relationships.

Reported herein are zero-lift total-drag data for nine models of the same configuration. Base-drag data were obtained on five of these models. Five of the models were half the scale of the other four, which are designated full-scale models. Some of the models were used concurrently for investigation of heat-transfer and boundary-layer phenomena at high Reynolds numbers in supersonic flow.

The Mach number range of the data presented is from approximately 0.85 to 3.30 for the full-scale models and 0.90 to 3.02 for the half-scale models. The Reynolds number ranges were from  $14 \times 10^6$  to  $210 \times 10^6$  for the full-scale models and  $15 \times 10^6$  to  $110 \times 10^6$  for the half-scale models. These Reynolds numbers are based on body length.

## SYMBOLS

- $C_{DT}$  total-drag coefficient, based on maximum cross-sectional area of the body (0.785 sq ft for full-scale and 0.196 sq ft for half-scale)
- $C_{DB}$  base-drag coefficient, based on maximum cross-sectional area of the body

R	Reynolds number, based on body length (12.2 ft for full scale and 6.1 ft for half scale)
M	Mach number
$\left(\frac{\Delta p}{q}\right)_{\text{base}}$	base-pressure coefficient $\left(\frac{P_b - P_o}{q}\right)$
$P_b$	base pressure
$P_o$	ambient static pressure
q	dynamic pressure
D	diameter

### MODELS AND TESTS

The general configuration and body equations of the test models are given in figure 1. A photograph of the full-scale model is shown in figure 2 and photographs of both the full-scale and half-scale models in launching position are shown in figure 3.

The bodies were of parabolic-arc profile, the basic parabolic shape having a fineness ratio of 15. Cutting off the pointed stern at 81.25 percent of the full length to allow space for the rocket jet resulted in an actual body fineness ratio of 12.2. The four stabilizing fins were equally spaced around the stern. Their plan form was untapered and sweptback  $60^\circ$  with a total aspect ratio of 2.04. They had a 10-percent-thick circular-arc cross section normal to the leading edge. The thickness ratio in the streamwise direction was 5 percent.

The full-scale model had a body length of 12.2 feet and a frontal area, on which the drag coefficients are based, of 0.785 square foot. The half-scale model had a length of 6.1 feet and a frontal area of 0.196 square foot.

The models were all metal in construction, utilizing spun magnesium-alloy skins and cast magnesium-alloy tail cones to which the fins were attached.

All models carried internally a sustainer motor; one full-scale and all half-scale models also utilized various booster rocket motors to obtain high Mach numbers. The rocket motors used and maximum Mach numbers reached are given in the following table:

Models	Sustainer rocket motor	Total impulse (lb-sec)	Booster rocket motor	Total impulse (lb-sec)	$M_{max}$
Full-scale 1,2,3	6.25-inch ABL Deacon used in all models	19,800	-----	-----	2.7
Full-scale 4			6.25-inch ABL Deacon	19,800	3.45
Half-scale - A	Modified 3.25-inch Mk. 7 used in all models	1,720	3.25-inch Mk. 7	1,720	1.6
Half-scale - B			5-inch HVAR lightweight	4,900	2.1
Half-scale - C,D,E			6.25-inch ABL Deacon	19,800	3.1

The variation of Reynolds number with Mach number obtained in the tests is shown in figure 4. Two curves are shown to represent the Mach number-Reynolds number relation for the full-scale models, one depicting the variation for the unboosted models 1, 2, and 3, and the second the variation for the boosted model 4. There are three curves shown for the half-scale models, since each of the three types of booster rockets used resulted in a different altitude-velocity relation during flight. As can be seen, for a given Mach number the test Reynolds numbers of the unboosted full-scale models were approximately twice those of the half-scale models, while for the boosted full-scale model the Reynolds numbers were roughly equivalent to those of the half-scale models.

Data were reduced for the decelerating portion of the flight trajectory after rocket-motor burnout. Trajectory and atmospheric data were obtained from the NACA modified SCR 584 radar tracking unit and by radiosonde observations. Velocity and total drag were obtained from the CW Doppler radar as described in reference 3. Also, total drag and base drag were reduced from data telemetered to a ground receiving station by instrumentation incorporating a longitudinal accelerometer and a pressure cell.

Base pressure was measured inside the afterbody between the rocket nozzle and the skin by an open-ended tube located in the full-scale and half-scale models as shown in figures 5 and 6. The annular area around the rocket motor at the base was sealed from the forward part of the body to prevent internal air flow. The base-drag coefficient was computed as equal to the product of the base-pressure coefficient and the

ratio of the base area to the body frontal area, which is 0.367. This assumes that the measured base pressure acts over the entire area of the base.

### ACCURACY

Total-drag coefficient.- The random scatter of the total-drag coefficient points for any one model is very small, as can be seen in figures 7 and 8, even though some difference is apparent between the results of different models of the same scale. The results of models of the same scale do, however, determine a mean curve of total-drag coefficient from which the maximum discrepancy in total-drag coefficient at any supersonic Mach number is  $\pm 0.008$  or approximately  $\pm 3.5$  percent for the full-scale models and  $\pm 0.015$  or approximately  $\pm 6.5$  percent for the half-scale models. The accuracy of the mean curves is, however, believed to be much better than these maximum discrepancies, probably being around  $\pm 0.005$  over the supersonic speeds for both the full-scale and half-scale models. The accuracy in the transonic and subsonic speeds is somewhat less, probably being about  $\pm 0.01$ .

Base-pressure and base-drag coefficient.- The frequency response (ratio of recorded pressure to actual pressure) of the base-pressure measuring system, from the end of the base-pressure tube through the pressure instrument, was one up to frequencies of approximately 3 cycles per second and 5 cycles per second for the full-scale and half-scale models, respectively. Since the only oscillation in base pressure was that which occurred through the transonic speed range and had a frequency of approximately  $1/5$  cycle per second, these relatively low frequency responses were satisfactory. The time-lag constant for the pressure system of both models was less than 0.0007 second. At the lower Mach numbers investigated, the base-pressure-coefficient data are subject to rather high systematic errors, since the quantity  $(p_b - p_o)$  is of the same order of magnitude as the reliability of the telemetered base-pressure measurements. Although the systematic errors in  $\left(\frac{\Delta p}{q}\right)_{\text{base}}$  may be large, the scatter of the data indicates for transonic speeds a probable accuracy of  $\pm 0.03$  in  $\left(\frac{\Delta p}{q}\right)_{\text{base}}$  or, because of the area-ratio factor, an accuracy of  $\pm 0.01$  in  $C_{DB}$ . The probable accuracy of  $C_{DB}$  at  $M = 2.5$  is  $\pm 0.003$ .

Model contours.- The body coordinates of the test models were within 0.020 inch of the design values and the surfaces were smooth and highly polished at the time of launching. Changes in surface conditions

due to heating during flight are believed to have been small since the design of the models is such as to hold irregular expansions to a minimum.

## RESULTS AND DISCUSSION

Drag results for the full-scale and half-scale models are presented over Mach number ranges of 0.85 to 3.30 and 0.90 to 3.02, respectively, in figures 7 and 8. Both total-drag coefficient  $C_{DT}$  and base-drag coefficient  $C_{DB}$  are based on the maximum body frontal areas.

Total-drag coefficient  $C_{DT}$  as obtained from the Doppler radar is shown to as low a Mach number (i.e., distance out) as was covered by that instrument. At lower Mach numbers  $C_{DT}$  was determined from telemetered drag-accelerometer data except for full-scale model 2 and half-scale models C and D which experienced telemeter failures.

Good agreement in total-drag coefficient is shown in figure 7 between the boosted and unboosted full-scale models. This agreement in  $C_{DT}$ , obtained in tests of greatly different Reynolds numbers, indicates that the effects of Reynolds number change at a given Mach number on the drag of this configuration are small over the range  $40 \times 10^6$  to  $210 \times 10^6$ . This is also indicated by the agreement in  $C_{DT}$  of the half-scale models whose Reynolds numbers at a given Mach number were also somewhat different. The mean  $C_{DT}$  curve for the full-scale models shows a maximum  $C_{DT}$  of 0.26 at Mach number 1.04, gradually decreasing to 0.21 at Mach number 2.5, and then decreasing more rapidly to 0.17 at Mach number 3.3. The mean curve for the half-scale models shows a maximum  $C_{DT}$  of 0.25 at Mach number 1.05, gradually decreasing to 0.19 at Mach number 3.0. Measurements of boundary-layer characteristics made on the full-scale configuration, which are as yet unpublished, also show a significant decrease in friction-drag coefficient with increasing supersonic Mach number.

The curve of the base-drag coefficient  $C_{DB}$  for the full-scale models, presented in figure 7, was computed from base-pressure measurements made on only one model. The base-drag coefficients as determined from half-scale models A, C, D, and E determine a mean curve which shows roughly the same characteristics, though lower values than those of the single full-scale model. Both show a maximum coefficient in the transonic range and a minimum at about Mach number 1.2 for the supersonic speed range. As can be seen from the curves, the  $C_{DB}$  for the

full-scale model has an average value of approximately 0.04 and the half-scale mean curve has an average value of approximately 0.025. This difference in  $C_{DB}$  may be due to either the difference in Reynolds number at a given Mach number or to the difference in internal base configurations, which are shown in figures 5 and 6. As can be seen, the internal volume from the base forward to the base-pressure measurement tube contained between the rocket motor and the skin is as much as seven times as great, relatively, in the full-scale models as in the half-scale models.

The measured base-pressure coefficient  $\left(\frac{\Delta p}{q}\right)_{\text{base}}$  from which  $C_{DB}$  was calculated is shown for both full-scale and half-scale models in figure 9 along with a calculated curve of  $\left(\frac{\Delta p}{q}\right)_{\text{base}}$  for full-vacuum base pressure.

For comparison of the results obtained at different Reynolds numbers, arbitrarily averaged curves of total-drag and base-drag coefficients for both the full-scale and half-scale models are shown in figure 10. It can be seen that the curves of the total-drag coefficient for both models are similar, with the full-scale curve being higher by approximately 0.015 over the supersonic range to Mach number 2.5. Beyond Mach number 2.5 the two curves approach each other, reaching the same value of  $C_{DT}$ , 0.195, at Mach number 2.9. A comparison of the base-drag curves again shows the full-scale values to be higher by roughly 0.015 over the measured range and also shows that the curves tend to converge at higher Mach numbers.

Subtracting the base-drag curve from the total-drag curve for both groups of models yields curves of total drag of the forebody, including fins. The comparison in figure 11 of these curves shows that they are in good agreement, indicating at most, only small effect on the fore drag due to the Reynolds number difference between the full-scale and half-scale tests over the range of Reynolds numbers covered. This might be expected from the compensating character of the two probable major Reynolds number effects on body drag; that is, a larger percentage of laminar boundary layer on the half-scale models, and a lower average turbulent skin-friction coefficient on the full-scale body due to its higher Reynolds numbers. Since the components making up forebody-plus-fin drag were not measured individually, it was impossible to determine the effects, if any, of Reynolds number change on these components.

## CONCLUSIONS

The supersonic zero-lift drag of a parabolic body configuration has been measured on both full-scale and half-scale models. The test Reynolds numbers of the unboosted full-scale models were approximately twice those of the half-scale models, while for the boosted full-scale model, the Reynolds numbers were roughly equivalent to those of the half-scale models. Within the limits of the investigation, the results indicated the following:

1. The total-drag coefficient for both models reached a maximum at transonic speed and gradually decreased over the entire supersonic range, while the base drags were a maximum at transonic speeds and a minimum at about Mach number 1.2 for the supersonic speed range with relatively constant values over the rest of the supersonic range.

2. There is at most, only small effect on total-drag coefficient of the RM-10 configuration at a given Mach number due specifically to reductions in Reynolds number (based on body length) of  $20 \times 10^6$  to  $120 \times 10^6$  over the Reynolds number range from  $40 \times 10^6$  to  $210 \times 10^6$ .

3. The base-drag coefficient of the half-scale models was 25 to 50 percent lower than that of the full-scale model. This difference may possibly be due to either the difference in Reynolds number at a given Mach number or to differences in the internal base configurations between the full-scale and half-scale models.

4. The difference in base-drag coefficients would account for practically all the difference in the total-drag coefficients of the two models, indicating that the effects of Reynolds number change on the fore-drag coefficient at a given Mach number is small in the Reynolds number range of these tests.
